This report documents the research work done under the World Bank Aided India: Environmental Capacity Building Technical Assistance Project entitled “An Economic Analysis of Sustainability of Marine Fish Production in Karnataka”. This research results are based on the premise that the continued economic productivity of the fisheries depends upon the current biological and economic conditions and sustainability implications of continuing current exploitation rate and methods. The 1990s have seen global crisis in marine fisheries and maritime state of Karnataka is no exception. The modernization of fishing fleets and uncontrolled expansion of fishing effort are main reasons, for declining growth rates of total marine fish production.

First, the optimum level of harvesting individual fish species was estimated using single species model by computing the parameters such as stock, standardized effort, catchability coefficient, etc. The results indicated that most of the species are harvested very close to MSY level (biologically optimum) and beyond MEY (economically optimum) level.

In order to incorporate the multispecies multigear dynamics of the fishery and to incorporate multiple objectives of the fishery management authorities

Title of the project: AN ECONOMIC ANALYSIS OF SUSTAINABILITY OF MARINE FISH PRODUCTION IN KARNATAKA

Period of the study: April 1999 - August 2001

Principal Investigator: Dr. Ramachandra Bhatta, Associate Professor and Head, Department of Fisheries Economics, University of Agricultural Sciences (Bangalore) College of Fisheries, Mangalore 575 002 Fecib@sancharnet.in

Environmental Economics Expert (Consultant): Dr. Mahadev G Bhat, Associate Professor, Environmental Studies Department, Florida International University, Miami FL University Park, Miami, FL 33 199 E-mail: bhatm@fiu.edu

Research Fellows:

- Mr. Sridhar Komar Research Associate (6 months)
- Mr. Anand P. Nazerath, Junior Research Fellow (12 months)
- Mr. Anand P. Nazerath, Senior Research Fellow (12 months)
- Ms. Shilpakala K. Senior Research Fellow (3.5 months)
- Devika Rani N. Senior Research Fellow (13 months)
- Suguna M. Nayak Senior Research Fellow (3 months)

Budget: Sanctioned Rs. 700,000

Released amount:

- Draft Number 928838 dated 27 March 1999 Rs. 280,000.00
- Draft Number 512344 dated 18 February 2000 Rs. 210,000

Acknowledgements

The support of the Environmental Economics Research Committee (EERC) of the World Bank aided "*World Bank aided Environmental Management Capacity Building Technical Assistance Project*" of the Ministry of Environment and Forests, Government of India; New Delhi allowed this research to become a reality. The authors are grateful to the chairperson and members of the EERC for funding this research.

Really great support was rendered by the Central Marine Fisheries Research Institute of the Indian Council of Agricultural Research, Cochin in providing updated data on species wise gear wise fish production for different major ports of Karnataka.

We acknowledge the support of GAMS Development Corporation, 1217 Potomac Street, N.W. Washington, DC, 20007, USA, by providing us with **free** GAMS software for use in this project.

Reviewing the report entailed the efforts of several people. We specially thank Dr. Kirit Parikh of the Indira Gandhi Institute of Development Research, Mumbai and an anonymous referee for their help in improving the quality of the earlier version of this report.

The great help and moral support was provided by Dr. K Aruna Rao, Reader in Statistics, Mangalore University, Mangalagangothri through out the project period. We are thankful to his affection and technical support.

Especial thanks go to the research scholars of the project for their help in data collection, analysis, compilation and report writing.

1. Introduction

The marine fisheries are one of the major industries in coastal Karnataka. In the state's exclusive economic zone of 87000 sq. km., fishery resource is estimated to yield 425,000 tonnes per year (Government of Karnataka, 2000). Importance of the fisheries sector to the state and national economy is widely acknowledged. Its significance lies in three main areas: (1) as a source of animal protein for human consumption (2) as a source of employment and (3) as a source of foreign exchange earnings.

The extraction of fishery resources has undergone major changes in the last few decades. In the 1950s, the state fisheries were characterized by small-scale with fixed fishing gears such as shore seines. The total catch was low and the fish caught were destined for local markets. However, in the early 60s there was a shift in the preference towards more mobile fishing gears, which allowed the fishermen to actively pursue fish. In 1966, a scheme for the construction and distribution of trawlers was introduced through the Dakshina Kannada District Cooperative Fish Marketing Federation of Karnataka. In the following decades, as in other parts of the country, Karnataka adopted ambitious programs for modernization of fisheries.

The emphasis of the program was to increase fish production for domestic consumption and export. This had been sought through various devices such as motorization, port development and providing new boats and fishing gears. As a result, during the period from 1970s to early 1990s, fish catch increased at a record rate and became highly diversified in terms of species landed. As of now, more than 80 species are commercially harvested throughout the state's coast. Fishing technology also was highly diversified. As per the latest estimates, there are more than 2098 shrimp trawlers, 378 purse-seiners, 1180 gill-netters, 1179 other mechanized boats, and 11958 non-mechanized boats (Government of Karnataka, 1997).

The fishery modernization in the state has had mixed results. On the one hand, despite the growing size of the fishing fleet, the industry has by no means attained its full potential. For instance, the Karnataka's average annual fish landing has remained around 142,000 tonnes in over the last 10-15 years, much below its

estimated total annual potential of 425,000 tonnes. On the other hand, there are growing signs of biological and socio-economic un-sustainability that threaten the coastal fisheries. The introduction of trawlers has adversely affected other shore seines' and its own catches. The Karnataka State Department of Fisheries reported symptoms of over fishing in shrimp and other high valued fishes (Government of Karnataka, 1997). Also, trawlers are alleged to have interfered with the fishing rights of traditional, small-scale fishers in the near shore areas, leading to rising social rifts between the two groups. The traditional rampani nets, which once accounted for 50-60 percent of the annual catch, have almost disappeared. There were episodes of clashes over resource users, which sometimes resulted in the loss of assets (Bhatta, 1996).

In the meanwhile, realizing the possibility of overexploitation, particularly along the inshore, the state government enacted the Karnataka Marine Fisheries (Regulation) Act (KMFRA) as early as 1986. The Act empowers the State Fisheries Department to regulate fishery through licensing. The overall package seems to prescribe limited entry, a standard policy instrument. The Act also has banned mechanized fishing during the Monsoon, which is the breeding season for most of the pelagic species. In addition to compulsory registration of vessels, this legislation imposed restrictions on fishing in specified areas, and on the number of vessels in specified areas and seasons. The compulsory registration of all the vessels both mechanized and non-mechanized also served as an authentic record on the number of various types of fishing vessels operating from the coast.

However, most part the Act was not vigorously enforced by the state government because of socio-political reasons, including widespread unemployment outside the fishery sector and lack of occupational and geographical mobility among fishing communities. Further, the costs of looking for alternative employment were high because of low education, cultural taboos and high indebtedness among fishers. One of the major difficulties faced by the fishery managers was the lack of quantitative information on the likely impact of fishery regulations on the output, income and employment levels in various fisheries and non-fisheries sectors.

After 15 years of KMFRA implementation, a number of issues still confront fishery managers in Karnataka, including the lack of better understanding of the fishery-wide

impacts of regulations, conflicts between small and commercial fishers, and declining stocks of certain fishes. The fishery regulation has never been based on a scientific understanding of how certain policy instrument might affect the biological sustainability and economic viability of target species. Species vary widely in their economic and biological productivity. Also, the technical efficiencies of different gear types are not the same. In a fishery that produces multiple species obtained through different types of gears, there could be technical interactions among species and gear types. The limited-entry policies of KMFRA do not seem to recognize these technical interdependencies among species and gears, or the productivity differences across gear types. Such policies only have the illusion of keeping control over the total fishing effort. They could still fail to stem the depletion of certain primary or secondary target species. No effort has been made as yet to analyse the biological and economic effects of alternative management policies on different species.

Objectives

This research is an attempt to address certain management-related questions concerning the process of fishery modernisation and the concurrent regulations in Karnataka. The key research questions we ask include:

- What are the current biological and economic conditions of commercially important species in Karnataka?
- What are the future sustainability implications of the current level of fishing effort?
- If the current levels of fishing are not bio-economically sustainable, what policy options are there for the fishery management?

Answering these questions entails some important analytical tasks. In order to address these questions, we need to develop appropriate analytical tools to first estimate stocks and stock-effort-catch relationships, and then to characterise the optimal mix of fishing fleets under alternative management scenarios. Such an exercise is hoped to better inform the management process in its effort to move toward more sustainable fishing.

The Regulations for Fisheries Management

The ultimate objectives of regulations aim at increasing the productivity of the stock and the net economic yield, which is the maximum difference between total cost and total revenue of the yield. The sole fishery manager would be interested in expanding fishing effort up to the point of maximum rent, which lies before the maximum sustainable yield point. The maximum economic yield (MEY) is preferable to the maximum sustainable yield (MSY) both from the economic and ecological point of view. The regulatory mechanisms usually adopted are:

- Regulations such as gear selectivity and seasonal and area closures.
- Regulations that control the fishing effort and catching.

The first fishery regulation was enacted in 1897 to control destructive fishing activities in both marine and inland waters. It explicitly banned the use of explosives and poisons in harvesting fish. However, until 1970s the state governments did not find the need for controlling fishing effort, as the fishing was mostly artisanal in character and mechanized fishing was negligible. With the rising foreign and domestic demand for shrimp and other fish products private firms from outside the exploitation of traditional fishing communities saw a good opportunity for financial profits in the exploitation of marine resources. Modern mechanized trawlers were rapidly introduced in Karnataka with state and central subsidy programmes through cooperatives and commercial banks. During the early years most of these fishing units operated by domestic firms from within and outside the local communities. Thus the influx of large number of big trawlers in the early eighties the fishing pressure on the marine fishery resources increased tremendously leading to eventual stagnation of catch and decline of average profitability.

Modelling Sustainability of Fish Production: Insight from the Previous Studies

Fishery resource management is perhaps a widely discussed topic in natural resource studies. Scott (1979) and Panayotou (1982) discussed the basic bio-economic and social rationality of various fishery management regulations. Based on the conventional economic wisdom, “common property” and the associated

economic inefficiency (Ciriacy-Wantrup and Bishop, 1975), a societal argument for fishery regulation is widely made. To quote Charles' (1988) conclusion from his review of various studies "... Left to their own devices, fishermen will destroy any social benefits that a fishery could produce. This conclusion, based on the assumption that fishermen are individualistic and myopic profit maximisers, has led to the wide spread advocacy of measures to reduce the number of fishermen and "rationalise" the fishery".

Panayotou (1982) identifies broadly two parameters, which the fishery administrators have tried to manipulate: (a) the age or size of fish at first capture, and (b) the total amount of fishing effort. The ultimate objective of both the approach is to increase the productivity of the stock and net economic yield. The respective regulatory instruments usually adopted are: (a) regulations such as gear selectivity and seasonal and area closures which aim at affecting the size and age of fish caught, and (b) regulations such as catching capacity controls and catch quotas which aim at affecting the amount of total effort or the quantity of catch.

The productivity and sustainability of measuring the marine fish production cannot be done in the same way as the productivity of the land or forests. The fishery catch depends on the stock of fish in the fishery grounds as well as on inputs in terms of fishing efforts and quantity of fishing gear used. In order to measure the changes in the productivity over the years we need the historical data on catch, effort and gear (Parekh and Parekh, 1997).

As evident from the above overview, an understanding of the losses of fish productivity over the years is required for the development of fishery management plan so that the gears which cause un-sustainability could be identified and a plan to reduce them would involve a temporary reduction in the income and employment of the fishermen and other post harvest enterprises. This requires a careful examination of alternative policy regimes, including various forms of limited entry under multi-objective framework. Each of these plans must be evaluated in terms of three broad objectives: long-term resource survivability, efficiency and equity. Such analysis needs to evaluate the impacts that alternative management plans would have on various interest groups, including large fishermen, indigenous artisanal fishermen, fishery labourers, processors, retailers, fishery regulators and consumers.

In order to accomplish an objective evaluation of complex, multi-objective fishery management, a suitable analytical framework is essential.

Onal *et al.* (1991) give a quick review on fishery management modelling studies. In the early history of scientific fishery management, the biological concept of maximum sustainable yield (MSY) was used as an accepted criterion. However, this criterion does not include economic consideration. Moreover, under conditions of natural variability and multi-species fishery, fishing effort guided by MSY principle becomes “too risky”. Economists developed approaches that maximise economic benefits subject to biological properties. Griffin *et al.* (1976) used an analytical model of Gulf shrimp industry to maximise overall rent given constant prices, cost functions and yield-effort relations. This approach failed to recognise inter-temporal and spatial aspects of fishery population.

Recognising the dynamic nature of fishery population, economist found optimal control theory and dynamic programming highly suitable tools (Clark, 1976; Clark and Munro, 1975; Sadeh *et al.*, 1989). Clark (1982) illustrated the use of optimal control model under a variety of regulatory policies, such as no regulation, total catch, restricted access (i.e., vessel licenses), allotted vessel quotas and taxes. However, most of the studies that used above approaches suffered from restrictive assumptions and failed to cover the complex mix of biological, economic and social aspects.

An alternative analytical tool adopted by fishery economist is linear programming (LP) (e.g. Rothschild and Balsiger, 1971). The validity of LP models to fishery is criticised in literature (Onal *et al.*, 1991). The LP approach suffers from classical problem of linearity assumption while non-linearity is frequently observed in catch-effort-stock relationship. Further, prices, cost and stocks usually are considered constant and exogenous in these models. Exogenous stock assumptions assume away the fundamental aspect of overexploited fishery-dynamic change in stock owing to fishing effort (Onal *et al.*, 1991). A non-discriminatory fishing effort applied to a given stock at a place and time influences stock abundance, productivity and size composition at other places and future. In a multi-species tropical environment, it is hardly possible to allocate the overall fishing effort between the constituent

species of the total fish stock. Therefore, a proper model must consider endogenous catch-effort-multispecies stock relationship.

Griffin *et al.* (1983), Grant and Giffin (1979), Nance and Nichols (1987) developed bio-economic simulation models that explicitly considered nonlinearity in catch-per-unit effort. A practical advantage of such models is their ability to generate biological data that generally are not observed. Onal *et al.* (1991) adopted a nonlinear price-endogenous programming model, following Mc Carl and Spreen (1980). The model incorporated endogenously - derived market demand functions. Biological characteristics of the system and endogenous catch-effort-stock dynamics entered the model as constraints. Anderson (1984) developed a policy-endogenous fishery model, called bioregonomic model. In addition to economic and biological aspects this model endogenously determines the type and level of fishery regulatory measures.

Most of the above analysis focused on a single objective rent-maximisation. While the need for including other social aspects of fishery has long been recognised, formal effort to apply analytical economics to realistic multi-objective fishery problems is minimal. Hannesson(1981) refers to few multiple goal programming studies conducted on Norwegian fisheries. Bishop *et al.* (1981) proposed multi-attribute portfolio analysis as a valuable analytical tool. However, as Charles (1988) notes, the results of such multi-objective analysis are useful only if appropriate weightings are assigned to each of these objectives.

Developing effective measures of social indicators such as income distribution and employment is critical task that often concerns fishery analysts. Charles (1988) provides a good review of studies that developed various measures of income distribution. Several studies in Panayotou (1985) attempted to measure the socio-economic conditions in small -scale Asian fisheries. While these studies provide useful descriptive information about sociological conditions of a particular fishing community, this information needs to be further integrated into a multi objective analytical framework. Such modelling effort should enable policy analysts to objectively measure the interactions between income distribution, resource productivity and overall industry behaviour under alternative economic and policy scenarios.

The modelling framework developed in this study attempts to integrate mainly technological, economic and biological aspects of the Karnataka fisheries. The main purpose of the analysis is to investigate if the current harvesting mix is economically and ecologically sustainable, and if not, to further suggest suitable adjustments to existing technology regime in order to help fisheries make a transition toward sustainability. The model, however, can be easily modified to incorporate equity and other social aspects concerning the fishery production sector.

In this study we employ both single-species static models (see chapter 3) and multi-species dynamic (mathematical programming) model (see chapter 4). The purpose of the first set of models is two fold. First, these models would enable us to assess the sustainability of individual species at the state level. Second, these models provide various techno-economic and biological parameters and stock estimates required for the multi-species programming model. Multi-species model is designed for individual port-level. A state-level multi-species model would not be appropriate since there is a large variation across ports. Casting the entire state into a single model might yield huge aggregation error.

The rest of the report is organised as follows. The next chapter presents an overview of the Karnataka fisheries that includes a brief description of the study area, the current fishery trend and exogenous forces that influence the state fishery industry. Readers who are familiar with the state fisheries may skip this chapter. The third chapter presents the analysis of a single-species model at the state level. In the subsequent chapter is presented the conceptual and empirical framework for a multi-period, multi-species programming model for a specific fishery management unit. The final chapter draws policy conclusions from the empirical analyses.

2. Karnataka Fisheries: An Overview

Background of the study area

The coastal ecosystem of Karnataka is a mosaic of monsoon wetlands, beaches and mountains--some as high as 2000 meters--stretched along its 300 km long shoreline. The coastal eco-region of the state is separated by Western Ghats connected by a number of rivers that form vast estuaries. Coastal wetlands do serve as an important source of economic livelihood for the local communities. This coastal region provides fishery and plant products, water supply to urban and rural population, flood control, erosion buffering, wild life habitat, recreation and tourism. The vast natural resource base of sea and estuaries generates income in millions of rupees, which unlikely is sustainable due to the over exploitation of resources and ill-conceived projects. In the last 15 years, more than 17,000 hectares of area and 50,000 people were displaced in coastal region of Karnataka due to industrial projects such as harbour, refinery, naval base (sea bird) and hydro electricity projects (Central Water Commission, 1996).

The states fishery resources potential is estimated at 425,000 tons per year over an exclusive economic zone of 87,000 km² (Bhaktha, 1983). In addition to marine fisheries, coastal Karnataka also has a large potential for brackish water fisheries. Several major rivers originate in the Western Ghats and their tributaries flow through two coastal districts into the Arabian Sea, forming a mosaic of more than 8,000 ha of estuaries along the coast.

Traditional fishing was undertaken using indigenous techniques with non-motorized boats, and thus could be characterized as a subsistence economic activity. In the last 20 years, fishing technology has widely undergone mechanization with the help of government patronage and the introduction of multinational corporations in Indian waters (Kurien, 1995). However, modern technology and capital have been accessible to only a small group of fishers. A large class of traditional, small – scale fishers either continued to operate with indigenous techniques or worked for modern fishing farms, and thus have not reaped the benefits of fishery mechanization (Acharya and Acharya, 1995). Modern fishing vessels initially operated only in inshore waters and over – exploited the fishery resources. This depletion adversely

affected fishing opportunities for small-scale, indigenous fishers and the traditional nets which once accounted for 50 –60 percent of the annual catch (Government of Karnataka, 1994a; Bhatta, 1996). These fishers have therefore been forced to depend more on inland or estuarine species, or to seek employment with large fishing firms.

Even though fisheries are an important economic activity in coastal Karnataka, this region is still predominantly agrarian because about 60 percent of all workers are dependent on agriculture and allied activities for their livelihood (Government of Karnataka,1994b). A major portion (71 percent) of croplands is cultivated for food-grain production. Rice is the leading crop followed by peanuts and horticultural crops.

Growth of transport, communication, electricity, education has resulted in rapid urbanization and in employment opportunities in secondary and tertiary sector. It is estimated that the district has about 1,50,000 transport vehicles, 243 km of national highways, 696 major factories and 10,250 small-scale industries. These industries directly employ 50,000 and 1,10,000 persons respectively (District Statistical Office, 1998). Many mega industries such as oil refineries, fertilizer plants, harbour, iron and steel plants were established during 1980's and 1990's which have attracted migration of skilled and unskilled workers from outside the state. Thus, there has been a tremendous growth in the industrial sector and is considered as one of the potential growth centres of the country. In 1996-97, at current prices the secondary sector generated a gross income of Rs.1,09,751 lakhs, which is nearly 30 percent of the total GDP of the district. The per capita GDP of the district is Rs.12,971 which is second highest in the state next to the state capital, Bangalore (Government of Karnataka, 2000). The net domestic income of the district (at 1980-81 prices) from the secondary sector was Rs.22,290 lakhs which is 7.5 percent of the state total income from the secondary sector.

Current status of marine fish production in Karnataka

Marine fisheries are increasingly becoming one of the highly globalized sectors of the world economy. The value of international fish exports, which was only US\$ 17 billion in 1985 has almost trebled to US\$ 47 billion in 1994 (FAO, 1998). The

increase in fishing effort since 1950s has led to rapid increase in global landings, which grew by an average of over 6% per year until 1970s. In 1990s the slow increase in landings turned into stagnation, though masked by an increase in aquaculture production (Liao, 1997). Neo-classical economic theory states that induced scarcity of these fish should lead to an increase in their price more rapidly than those of their more abundant substitute (Gravelle and Rees, 1981). Such increase given the functioning of markets would then lead to rewards for conservative fishing practices, enabling continuous landings of the highly priced commodity. However, empirical evidences do not clearly support this theory.

The Indian marine fisheries is no exception to the global trend. The marine fisheries operations in the pre-independence days used to be carried out at a subsistence level, almost exclusively by the traditional fishermen. Today, this sector has attained the status of a capital-intensive industry, warranting close monitoring and management for sustainable development (Devaraj and Vivekanandan, 1995). In the course of the past five decades, the annual marine fish production of India increased from about 0.9 million tonnes in late 60s to the current level of 2.6 million tonnes (Table 2.1). Table 2.2 presents the group wise growth in annual fish production of Karnataka from 1969 to 1998. The table shows that the total fish production increased from 75,793 tonnes in 1969 to 2,51,012 tonnes in 1989 and started declining thereafter with a production of 1,39,676 tonnes. The contribution of annual pelagic fish production varied between 80 percent in 1975 to 50 percent in 1994. The percentage of demersal fishes varied between 9 percent in 1971 to 30 percent in 1983. Crustaceans, which accounted for a small proportion, during 1970s increased its share to 25 percent in 1987 and declined thereafter.

Table 2.3 presents the relative growth of the different species groups from 1969 to 1998. The table indicates that the relative growth was high for all the groups except for crustaceans during the period 1969 –74 to 1975-80. During 1981-86, the relative growth of molluscs production declined from the previous peaks. With higher concentration of effort on crustaceans due to increase in international market price led to an increase in production with a relative growth rate of 188 percent.

During 1987-92, the relative growth rate of demersal and crustaceans decreased and the miscellaneous group was further reduced. During the period of 1995-98 all the groups have shown negative growth except molluscs.

The species wise landings of pelagic for the period of 1970-98 are reported in Table 2.4. The average annual landings of oil sardine declined from 33,834 tonnes during 1970 to 8697 tonnes in 1998. Similarly anchovies, mackerel etc. are showing declining trend. Among pelagic species Tunnies, Ribbonfishes etc shows the increasing trend. But the total pelagic landings gradually decreased from 87,541 tonnes in 1970 to 78,161 tonnes during 1998.

The landings of demersal species reported in Table 2.5 shows much serious impact of commercial fishing. The production of sharks, catfish, perches etc. are showing declining trend. The landings of molluscs (Table 2.6) shows that the overall production of these export oriented species have increased by 3 times from 2287 tonnes in 1990 to 7271 tonnes in 1998. The increase in the export demand reflected in higher price has boosted up the production.

The growth in the production of crustaceans (Table 2.6) shows two different scenarios. The production of traditionally export-oriented species such as penaeid prawns and Lobsters is declining in recent years. The production of shrimps doubled from 3098 tonnes in 1980 to 6688 tonnes in 1990 with the introduction of trawlers in inshore and offshore waters. However the signs of over harvesting is reflected indicated by the decline in the total landings itself apart from other signs. Some of the other species such as Crabs and Stomatopods gained export importance during early 1990s and with the concentration of more effort on these species the production though increased initially also have started declining in recent years.

Trend in marine fish production

The growth rate of annual fish production was estimated using the simple log linear growth function $Y = AB^t$, where Y = Annual fish production; A and B are estimated parameters and t is years. The estimated growth rate for the entire period of 1969-98 for individual group is presented in Table 2.7. The overall growth rate of pelagic, demersal, molluscs and crustaceans were 1.35%, 4.05%, 25.04% and 6.68% respectively. The overall growth rate of total production was 2.16 percent. This slow

growth rate in pelagic species, an important commercial category, is at best an indication that the commercial fishery production is slowing down in the state.

The growth in the number of fishing vessels, which represents the intensity of fishing, is presented in Table 2.8 and 2.9. In contrast to the growth in fishery production, the total number of mechanised fishing boats doubled during the last two decades. During the corresponding period, the number of non-mechanized boats also increased. All most all these non-mechanised boats are motorised and fitted with outboard engines. The increase in the number of boats is also coupled with the enhancement of fishing capacity in terms of size (OAL), engine horsepower, electronic equipments etc. that is not properly reflected and quantified. Thus, one of the most important reasons for non-increasing landings could be over harvesting.

Environmental factors affecting fish production

The coastal environmental parameters are important for the growth of fisheries and are showing signs of degradation. Table 2.11 shows the quantity of effluent discharges from the mega industries into the coastal waters of Mangalore. The effluent discharged by these mega industries includes heavy metals, which are harmful to estuarine/coastal fisheries. However, the direct impact of these discharges on the population of aquatic animals has not been studied. On the other hand, it has been well documented that the composition of fish species has been changing over the years.

Some of the species such as fishing cat, otter, estuarine-crocodiles are now rarely found and are included in Schedule I (Endangered and highly protected species) of the Wild Life Protection Act (1972). Some of the grasses grown in tidal rivers of the district are recorded as extinct and included in IUCN Red Data Book of Rare and Endangered Plants (Hussain and Achar, 1999).

Conclusion

Karnataka is one of the most important coastal states contributing 5.23% of India's total fish production. Pelagic fisheries contribute around 60 percent of the total fish production in terms of the quantity followed by demersal (16%) crustaceans (13%) and molluscs (2%). The result of the time series data analysis indicates that the

mechanization of the fishing technology has improved the catch during the 1970's to early 1980's. However symptoms of over fishing was observed during early the 1990s, as shown by decline in the growth rate of total fish production. The fishing effort in terms of the number of fishing units has doubled over the period of two decades. The commercial fishing is also seriously affecting species composition shifting from the high valued target species to low valued species. The data environmental parameters and pollution discharges from mega industries show that over the years the stress on coastal and estuarine fishes has increased.

3. Single-Species Model

The marine fish production comes from the interaction of two main systems: the biophysical and institutional environments. Various interactions within the biophysical environment and its fluctuating nature due to climatic changes make fishery production highly complex to understand. Human intervention into fisheries makes the system even more complicated. For instance, the stock externalities arise from the actions of fishers who fail to account for the costs they inflict on other fishers, operating the same and other types of gears as they harvest (Smith, 1968). That is, when a fisher harvests fish under an open-access regime, the level of fish stock decreases, and thus, increases the harvesting costs for other fishers. The harvesting cost increases because of the increase in the amount of search when there are too few fish. By not having to internalise these external costs to others, fishers expand their effort beyond the economically efficient harvesting level.

Another common problem with fisheries is technological externalities (Gardner *et al.*, 1990). This externality arises when different types of gears entangle each other or they interfere in the flow of fish to other fishing gears. As a result, gear is either not fully utilized or destroyed in the operation. Finally, the problem can also arise in the form of lack of assignment (Gardner *et al.*, 1990). The fish are unevenly distributed across different fishing grounds, and they concentrate in those areas where more food is available. If the number of fishers in each such spot exceeds the number that that spot can afford, the conflicts arises over the access to such spots among fishers.

The policy objective of most fishery management has traditionally been to maintain individual species stock at some sustained level. How and whether this policy goal can be actualised will depend on the institutional arrangements that exist for a given fishery. In most of the developing countries fisheries are open access resources with little or no regulation. Under this type of property rights, fishermen will apply effort until the point of zero rent. Since the fish stocks are jointly harvested, stock externality arises, and there is less incentive to conserve the resources for the future. Scott (1955) argues that the fishers harvesting from the open-access fishery heavily

discount the future. Fishers maximise current returns instead of the future flow of fish.

Although Karnataka laws provide for regulating open access fishery, the enforcement has been inadequate. This makes one wonder if some of its commercial species have been already overexploited. It is equally likely that some species remain under-exploited as fishing effort might focus on a few commercial species. The primary objective in this chapter is to analyse the current status of major commercial species, specifically by estimating level of their current exploitation vis-a-vis sustained yield levels. The analysis is done for each species individually at the state level. A simple fishery bio-economic model is employed to estimate the indicators of sustained yields.

Bio-economic Model of Fishery

Resource managers have used two distinct measures of sustained yield for managing fisheries, depending on the underlying management goal. According to biologists, the optimal management goal would be to harvest fish at maximum sustainable yield (MSY). On the other hand, economists would advocate exploiting fisheries at maximum economic yield (MEY). While MSY results in the maximum quantity of catch of a given species each period, it normally is not economically efficient. The effort generating MEY results in the maximum annual net profit. By definition, both these yield levels have their corresponding effort levels that keep stocks sustained year after year, given everything else unchanged. In the context of tropical capture fishery, biological data such as fish growth, mortality, age class and stock recruitment required to set up the advanced model are not available. Therefore, simple model such as surplus production model is more useful to analyse fishery dynamics (Sparre, 1991). In the present study, the Fox model is used to estimate MSY and MEY and their respective effort levels. The Fox model is a modified version of Schaefer's model (Fox, 1970), in which a logarithmic relationship between catch per unit effort (CPUE) and fishing effort (E) is formulated as $\ln(CPUE) = f(\text{effort})$. More formally,

$$\ln\left(\frac{Y}{E}\right) = a + bE \quad (3.1)$$

where Y is total annual catch, E annual fishing effort, and a and b are constant parameters.

The level of effort that generates MSY can be obtained from equation (3.1) easily. Exponentiating both sides of (3.1) and solving for Y , we have

$$Y = Ee^{a+bE} \quad (3.1a)$$

Differentiating Y with respect to E in the above equation, setting the result equal to zero, and solving for effort (E_{MSY}) that maximises Y (i.e., that returns MSY), we obtain

$$E_{MSY} = -\frac{1}{b} \quad (3.2)$$

The corresponding MSY can be obtained by substituting equation (3.2) into equation (3.1a). That is,

$$MSY = -\frac{1}{b}[e^{(a-1)}] \quad (3.3)$$

The maximum sustainable yield (MSY) is what biologists try to shoot for while setting targets for fishing effort. With the increase in effort, the growth in the size of sustainable catches will be smaller until the effort reaches the point corresponding to the MSY. Beyond this point, each additional effort reduces sustainable yield.

Maximum Economic Yield

As mentioned earlier, managing fisheries at its biological maximum or MSY may not prove to be economically efficient. Integrating economic considerations such as fishery input and output prices with the biological and technical aspects discussed above becomes essential in order to maximise fishery net returns. A simple economic model introduced by Gordon (1954) is quite handy for this purpose. To begin with, in this model, fishery input and output values are expressed in terms of total cost and total revenue and as functions of fishing effort. The total cost consists of two parts i.e. fixed and variable costs of fishing effort. The fixed costs consist of costs required before any direct fishing effort is made. The variable costs consist of all the costs required directly to operate the fishing effort, such as fuel, food and labour. With this assumption costs per unit of fishing effort (c) is constant. Hence, the

relationship between the total cost and fishing effort would be linear. This means average and marginal cost would be identical.

The total cost of fishing (TC), marginal cost (MC) and average cost (AC) can be written as:

$$\begin{aligned} TC &= cE \\ AC &= MC = c \end{aligned} \tag{3.4}$$

where c is the cost of unit effort. Price in fishery can be considered either as fixed or variable depending on the type of product market. To keep the analysis simple and for the lack of better data, most studies in the past have assumed fixed output price. The assumption of fixed price is reasonable because it is determined by such uncontrolled factors as weather, environment and resource availability. This assumption implies that fishers in the study area are price takers and their supply will not affect the market price by any significant measure (Anderson, 1979). This also implies that the dynamics of the fishery can be described in terms of supply adjustment in response to price levels. This, in turn, indicates that any regulations on the fishery will only affect producers.

In the steady state condition of the Schaefer model, the sustainable catch curve is the long-run production function for the fishery from an economic point of view. This means that at any particular level of fishing effort the quantity of fish produced from such a resource is on a sustainable basis.

From an economic perspective, analysis of these relationships focuses on average and marginal sustainable catches. From this standpoint, the average and marginal sustainable catches are defined as the ratio between total sustainable catch and fishing effort and the change in sustainable catch due to a change in fishing effort, respectively. Assuming a fixed price p for the fish caught and using equation (3.1a), total revenue (TR) and marginal revenue (MR) functions can be expressed as:

$$TR = pY = pEe^{(a+bE)} \tag{3.5}$$

$$MR = p(bE + 1)e^{(a+bE)} \tag{3.6}$$

The maximum economic yield (MEY) occurs at point of effort where the net profit from fishery is maximum. Using the simple marginality principle, MEY can be determined by equating equations (3.4) and (3.6), i.e., setting $MR = MC$. Thus,

$$p(bE + 1)e^{(a+bE)} = c \quad (3.7)$$

By further simplification,

$$(bE + 1)e^{bE} - \frac{c}{pe^a} = 0 \quad (3.8)$$

The above equation is in the form $f(x) = 0$, where $x = bE$. Using Newton's method of successive approximations, if $x_1, x_2, \dots, x_n, x_{n+1}$ are the real root of the $f(x) = 0$, the successive roots are given by

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}, \quad \text{for } n = 1, 2, 3, \dots \quad (3.9)$$

Hence we suppose x_1 (for $n = 1$) to be near a root of the equation $f(x) = 0$, putting this value of x_1 in equation (3.9) we get x_2 . Then putting this value of x_2 (for $n=2$) in (3.9) we get x_3 and so on. By successive operations we get a close approximation of the roots. This routine algebraic simplification solves equation (3.8) and yields an expression for the effort (E_{MEY}) that returns MEY.

$$E_{MEY} = \frac{1}{b} \left[-1 + \sqrt{\frac{c}{pe^a}} \right] \quad (3.10)$$

Knowing E_{MSY} , one can compute MEY using equation (3.1a) as follows:

$$MEY = E_{MEY} e^{(a+bE_{MEY})} \quad (3.11)$$

Note that the MEY effort is generally below the MSY effort. On the other hand, the sustained stock associated with MEY is greater than the stock corresponding to MSY. Thus, some economists believe both from economic and biological viewpoints, the management program that targets MEY is superior to that does MSY.

In order to estimate MSY and MEY, we first need to estimate the Fox model in equation (3.1). The Fox model at best applies to the case of single-species. However, in a multiple-gear, multi-species fishery like the one under study, the independent variable effort is not observed for each species individually. Therefore, one needs to first compute this variable by aggregating the pro rata effort of all different vessel types dedicated to a given species. The procedure employed for this aggregation is explained further in the chapter.

The value of landings used in equation (3.10) and (3.11) is ex-vessel prices. Ex-vessel prices are those received by fishermen for different species and sizes of fish, which generally fetch different prices. However, in this study the average ex-vessel prices for each species was considered. The cost of fish harvesting is assumed to increase proportionately with fishing effort. We have considered only operational cost of fishing and capital cost was not considered (Hannesson 1993). With those definitions, the relationships may be presented graphically as shown in figure 3.1

Figure (3.1) A fixed price model of fishery indicating MEY and MSY

Estimation of Stock

When we describe the dynamics of an exploited aquatic resource, a fundamental concept is stock, which means a group of fish species having the same growth and mortality parameters. The historical and current fish stock estimates are another set

of measures that one could use for assessing the sustainability of each commercial species in Karnataka. The current stock estimates can also serve as benchmark for analysing the sustainability implications of current and future management policies. Therefore, an attempt is made here to estimate the level of stocks of study species in the Karnataka coast. However, the real problem is that the tropical fisheries are characterized by a large number of different species. Often only some species are of economic importance, and the data may not be available for all species. Therefore, our analysis focuses a select number of economically important species.

Following Conard and Clark (1995), the annual harvest (yield) of a fishery can expressed as a function of fishery effort and stock (X) in each period. That is,

$$Y = f(E, X) \quad (3.12)$$

Y and X are measured in the same unit. A stylized production function commonly used in the fishery literature is

$$Y = qEX \quad (3.13)$$

where q is the constant parameter, called catchability coefficient (Clark , 1985), representing the proportion of stock captured by a unit effort. The method for estimating the parameter q is explained below. The knowing the values of q , an initial period's annual catch Y and effort E , one can estimate the value of initial stock. Then for successive years, stock may be estimated using the dynamic equation of motion,

$$X_t = (1 + \alpha)X_{t-1} - Y_{t-1} \quad (3.14)$$

where α is the annual net biological growth parameter, and t is the time period.

Catchability Coefficient

The catchability coefficient describes the effectiveness of each unit of fishing effort. The constant catchability coefficient for each species implies there is no change in technology over a certain period of time. Even though the catchability coefficient may vary with time, its time variance is difficult to measure (Sparre and Venema, 1992).

Based on the regression results of the Fox model (i.e., coefficients a and b), the value of q_t for a given period t can be computed as follows:

$$q_t = \frac{\left(z_t U_t^{1-m} + \frac{1}{-b} \right) \left(z_t U_{t-1}^{1-m} + \frac{1}{-b} \right)}{z_t m - z_t} \quad (3.15)$$

where $z_t = -\left(\frac{a}{-b}\right) - \hat{E}_t$

and $\hat{E}_t = (E_t - E_{t-1}) / 2$

From the individual years' catchability coefficients computed in (3.15), we can estimate the average catchability coefficient over n years:

$$\bar{q} = \exp \left[\frac{\sum_{t=1}^{n-1} \ln |q_t|}{(n-1)} \right] \quad (3.16)$$

q_t : estimates catchability coefficient

U_t : catch per unit of standardised fishing effort in year t

E_t : standardised fishing effort in year t

n : number of observation in year, $t = 1, 2, \dots, n$

m : constant parameter with a value of 1.0001 for the Fox model

\bar{q} : average catchability coefficient

a and b : estimates coefficients in the Fox model

Data Collection and Analysis

Selection of species and data collection

Karnataka is known for very rich marine biodiversity. It is estimated that around 310 different marine fish species are available in the coastal waters of Karnataka apart from other migratory aquatic animals (Madhyastha, 1998). During the year 1998-99 the total fish production was 160,000 tonnes with a catchable potential of 270,000 tonnes and with a continental shelf of 27,000 sq. km. From a list of species mentioned as commercially important by the Working Group of the Government of India, the following species were selected for our analysis. The selected species constituted 60 percent of the total landings in 1998.

The data for the descriptive and modelling part of Karnataka marine fisheries comes from mainly two sources. The landings and effort data for the period from 1994-98 was drawn from Central Marine Fisheries Research Institute (CMFRI). The CMFRI collects the statistics on marine fish production in major and minor landing centres of all the 11 coastal states. It uses the multi-stage stratified random sampling design for the estimation of marine fish production and fishing effort. Thus the basic material on landings and effort data was drawn from CMFRI data bank.

The second set of data on costs and earnings, harvested price, labour share and income, and other economic parameters were collected by conducting a sample survey of the fishery vessels in coastal Karnataka. The data were collected for the two coastal districts namely Dakshina Kannada and Udupi districts for the fishing season of 1999-2000. The costs of fishing trips, capital and fixed costs of crafts and gear were compiled from 15-20 fishing units in each vessel class to estimate the economic efficiency of each selected vessel. The table 3.1 shows the total number of different industries and the number of sampled industries in the study area. In most cases frequent visits to the fishing ports to observe the species landed, prices and cost of each fishing trips yielded much better data. Since fishing and fish harvesting takes place on a day-to-day basis unlike agriculture, such frequent observations were more useful in estimating accurate data. The market price data came from the published reports and documents.

Data development

Standardisation of fishing effort: Economists think of effort in terms of the boats, men, gear and so on. This is usually termed as nominal fishing effort and is expressed as fishing days or actual fishing hours. The fishing effort is proportional to fishing mortality. This creates problem when we have to compare the efforts from different gears. If two boats fish side by side during the same period of time and one of them catches twice as much, that boat is said to have double the fishing power. Obviously some boats or gears are more efficient in catching certain species than others. Hence, it was necessary to convert efforts of different vessel types to a standardised fishing effort before we could estimate various models and indicators discussed above. The vessel having the highest catch per unit of fishing effort (CPUE) is selected as the standard vessel. Then, the effort of other vessel of type, say Z, is given by the ratio of CPUE of vessel Y to CPUE of standard vessel, multiplied by fishing effort of Y.

The models and methods described in the standard literature have dealt mostly with a single stock exploited by one fleet. However, in the case of tropical fisheries this situation is an exception rather than a rule. In most cases a particular gear exploits several stocks, and several types of gears compete in exploiting the same resources. Thus we operate with three main types of interactions between the gears harvesting multiple species. The simplest way to deal with the multi-species and multi-fleet system is to apply the surplus production models to the total catch. However, we need to compute the aggregate fishing effort from all fleets on a particular species. This aggregate fishing effort on individual species is used for modelling and optimisation. The following four-step method was adopted to calculate the species-wise aggregate fishing effort.

Step 1: From the original CMFRI data on gear-wise, species-wise landings, calculate the proportion of species i 's catch to the total catch of vessel j . That is, the ratio of catch i from vessel j (C_{ij}) to total catch of vessel j (C_j). Call it d_{ij} .

Step 2: Multiply the total annual effort (E_j) of vessel j by d_{ij} to compute the amount of effort dedicated to species i by vessel j . Call it E_{ij}

Step 3: Standardise E_{ij} of all vessels by multiplying each of them with their respective effort standardisation parameter, s_j . The s_j is determined by taking the ratio of the $CPUE_j$ of vessel j to the $CPUE_m$, where m is the vessel having the maximum CPUE. The CPUE for each vessel is computed by taking the ratio of C_j to E_j . Thus,

$$s_j = \frac{CPUE_j}{CPUE_m} = \frac{C_j / E_j}{C_m / E_m}$$

Step 4: Aggregate the standardised efforts of all vessel types dedicated to each species to arrive at the total effort (TE_i) for species i .

$$TE_i = \sum_{j=1}^n s_j E_{ij} \quad \text{for species } i$$

Where n is the number of vessel types.

Step 3 above recognises that each gear has different efficiency levels in harvesting fish, and therefore, standardises efforts of participating vessels to a common denominator (Sparre and Venema, 1992).

Estimation of costs of production: The multi-species, multi-gear fishery operation presents similar complication, as discussed above, for estimating the species-wise unit effort cost. The following procedure was adopted to compute the same.

Step1: Find the unit vessel effort cost ($UVEC_j$) of each vessel j from the collected vessel data.

Step 2: Compute the total effort cost (TC_i) of species i using the following formula:

$$TC_i = \sum_{j=1}^n UVEC_j E_{ij} \quad \text{for species } i$$

Results

Fishing ports and their importance

Karnataka has 29 fish landing centres of which 13 are in Dakshina Kannada District (including Udupi) and rest are in Uttara Kannada district. These centres are spread along a coastline of 320 km. Out of the total landings of 160,627 tons of fish, 35

percent was landed in Mangalore port followed by Malpe (20 %) and Karwar (9 %) in 1998.

Table 3.2 shows that the proportion of landings in Malpe increased from 20 percent to 28 percent over the period from 1990-98 whereas there was a decline of 7 % in Mangalore port. However, in terms of effort 50-60 percent is concentrated in Mangalore port followed by Malpe (20-30 %), Gangolli and Tadri (Table 3.3). Table 3.4 presents the gear wise catch per unit of fishing effort (CPUE) from 1994-98. While the CPUE for trawlers, which mainly harvest high valued species, varies between 30-40 kilograms per hour, and for the purse seiners, it fluctuates over a very wide range as they harvest mainly pelagic resources. On the overall the CPUE varies in the range of 30-40 kilograms per hour of fishing.

Table 3.5 presents the catch per unit of fishing effort in different ports of Karnataka. Table shows that Mangalore, which has highest proportion of effort, has least CPUE followed by Malpe. Bhatkal and Gangolli had higher CPUE, which are relatively less dense in terms of effort.

Cost and Returns of Fishing Operations

It is well known that under the open access conditions of property rights, resource users tend to intensify capital accumulation in the production process in order to harvest the resources much faster. Further, increase in market prices could intensify harvesting even though the yield rate per boat might be decreasing. Tables 3.6 - 3.8 show the costs and returns of three major types of gears collected from previous research studies (Prabhakar S, 1991 and Aithal, 1993) as well as ones developed under the present study. It is evident that the costs have risen from 1988 to 1998. The capital investment cost has increased from Rs.6 lakhs to Rs.25 lakhs for purse seines, from Rs. 1.50 lakhs to Rs.14 lakhs for trawlers. The multi-day trawl fishing vessels introduced in early 1990s also shows a substantial increase within a period of 3 years. The investment cost of multi-day trawlers increased from Rs.14 lakhs in 1995 to Rs. 17.5 lakhs in 1998.

The operating costs, the major share of which is diesel and oil, also show a substantial increase in spite of diesel subsidy given by the state and central

governments. The increase in the operating costs is to the extent of 153 percent and 54 percent between 1988 and 1998 for purse seines and trawlers respectively.

The rising cost of production over time is a partial indication of declining productivity and stocks for some species. Overcapitalisation and crowding of fishers would result in declining stock and productivity, and in turn, increasing costs of production.

Standardized Fishing Effort

The total standardized fishing effort on each of the selected commercially important species (both pelagic and demersal) is presented in Table 3.9(a) and Table 3.9(b). Over the period of eight years, the standardised fishing effort for shrimp increased by more than 10,000 hours (AFH) and that of threadfin breams increased by more than 25,000 hours. Among pelagic species maximum increase occurred in the case of tunnies, followed by seer fish and other species. These results point to the fact even in a short period of eight years, there has been an escalation in fishery capital in Karnataka.

Catch – Effort Relationship

The analysis of total catch, effort and CPUE for the pelagic species is presented in Table 3.10(a). The Indian mackerel constituted major part of the catch among pelagic species. However, total landings decreased by 36% from 42821 tons in 1996 to 27257 tons in 1998. During the corresponding period the standardised fishing effort and CPUE also decreased. The fishing units experienced a loss of more than 123 kilo grams per hour from 550 kilo grams per hour in 1996 to 417 kilo grams in 1998.

The oil sardine another important species has shown a marginal improvement since 1995. Though total catch is showing marginal increase the CPUE is stagnating and there has been a decline in 1998 to the extent of more than 100 kilograms per hour. The total landings of *Stolephorus* also presents similar trend. Except in 1997, the CPUE has declined by nearly 50% from 622 kilograms to 353 kilograms. Other species such as tunnies, scads, hilsa shads, wolf herrings show fluctuating landings and CPUE. These species are harvested together with other species and their catch is relatively less.

The analysis of total catch, effort and CPUE for the demersal species is presented in Table 3.10(b). The catch, effort and CPUE for the threadfin breams shows that the increase in the effort was to the extent of 380% from 1994 to 1998 and the total catch has doubled from 5210 tons to the 13233 tons during the corresponding period. With the result, the CPUE declined by 58%. This trend was more permanent in catfish and sharks. The effort on sharks increased by two times and CPUE declined by nearly 3 times. Thus impact of increased effort on CPUE is clearly visible in the case of catfish and sharks.

The landings of pomfret on the other hand represent an example where the decline in the total catch has made the fishermen to reduce the effort leading to a marginal improvement in the CPUE. The total effort on shrimp, one of the most targeted species shows that total catch is stagnating and effort is declining. The CPUE is has been fluctuating around 150-250 kilograms per hour. Some of the field observations revealed that with average landings of Shrimp of 1500 kg's per trip of 6-8 hours during 1990's the current catch quantity has reduced to 1-5 kg per trip. Shrimp, which used to constitute 80-90% of the total catch quantity, today does not constitute even ten percent. Table 3.11 shows the cost of harvesting in Mangalore port by different gears. The table shows that the cost of harvesting per kilogram is lowest in purse seiners compared to other gears. But the cost per hour of fishing is low in gillnets and outboard fishing units.

Maximum Sustainable Yield and Maximum Economic Yield

The parameters of the Fox model used in the computation of MSY and MEY are reported in table 3.12(a) for demersal species. The R-square for most of the species were significant. The unit cost of harvesting and the market price for study species are also reported in the same table. It is evident that the difference between cost and price reflecting the surplus is highest for pomfret and shrimp followed by sharks and rays. Interestingly, the current harvest levels for these species have far exceeded the sustainable yield (Table 3.13(a)). Thus motivated by the higher economic surplus, the fishermen try to harvest more resulting in biological unsustainability of these resources. Table 3.12(b) presents the estimated parameter values for pelagic species. Since these species are short lined and highly fluctuating

the estimation is not accurate. The stolephorus, mackerel and tunnies have highest revenue surplus, as presented in table 3.12(b).

Table 3.13 (a) presents the estimated values yield, effort and cost of MSY and MEY level for the selected demersal species against the harvest quantities of the base year 1998. The table shows that for most of the species the current harvest has executed both MEY and MSY, indicating some degree of over exploitation. For example by spending 19183 actual fishing hours (AFH), the fishery could have harvested 8400 tonnes of MEY and 8327 tonnes of MSY. However, by spending almost the same level of effort (19719 AFH) the current yield (1998) was only 2516 tonnes which represented the excess of fishing effort and hence societal loss. In the case of many other species, the current harvest quantity is more than the MSY and MEY.

The estimated values of MEY and MSY pelagic fishes presented in table 3.13(b) show that for some of the species such as mackerel, the symptoms of unsustainability is very clear. By spending 67582 AFH an MEY level of 30848 tonnes could have generated maximum revenue surplus. However, the comparison with the 1998 yield and effort shows that by spending almost same level of fishing effort (65288 AFH) the yield is only 27257 tonnes indicating a decline in profitability.

The sustainability of demersal species in value terms under three scenarios is presented in table 3.14(a). Scenario 1 and 2 represent the value of catch with the restriction of MSY and MEY. That means if the fishery managers were to impose the restriction, the actual catch value should have been only Rs.786.01 millions of MSY or RS.736.79 millions of MEY. However the actual (1998) harvest value for most of the species have exceeded both MSY and MEY levels representing excess harvest value over and above the sustainable level, with a total of Rs.1540.32 and Rs.1615.41 of MEY and MSY, respectively. Table 3.14(b) presents the results obtained for pelagic species. The table indicates that for tunnies, seer fish and stolephorus, there has been an excess harvest over and above the sustainable level. Though accurate estimation of sustainability for these species is difficult because of the highly fluctuating nature of these species, the results indicate that they are also under threat from the viewpoint of sustainability.

Conclusions

Over the years the infrastructure development in fishing harbours and ports have attracted more and more mechanised fishing vessels into such ports. Mangalore with developed port infrastructure and access to urban centres has highest concentration of fish landings and effort. However, the concentration effort was much higher than landings indicating lower CPUE compared to other ports.

The concentration of effort on each species during the period of 1990 - 98 indicate that for all the species the standardised efforts have increased. This expansion does not take into consideration, the improvement in the technology with more and more electronic and fish finding devices. There has been a substantial growth in the standardised effort over a period of 8 years. The concentration of effort on high valued species such as demersal group (Shrimp, Breams, Soles) has increased. However, in the case of pelagic species, which are mostly used for domestic consumption and are relatively low valued, the increase in the total effort was not as high as for demersal. Indian mackerel constituted major share of the total production among the pelagics. However, both CPUE and effort decreased during 1990s, indicating symptoms of un-sustainability.

For most species in Karnataka, we find that the current level of exploitation is either close to or over the MSY level. Therefore, some species are being currently harvested at their biological optimums, but clearly they are way above their MEY levels or economically efficient levels. This only indicates that the state fishers are losing substantial rents from the fishery due to excessive capitalisation and overexploitation of resources. Avoiding such rent loss may require several measures, including retiring some fishery fleet, readjustment of efforts across species, seasons and/or gear types, and other technological changes. In the next chapter, with the help of a more location-specific, decision-support harvesting model, we can show how one can articulate the above rent-loss reduction goal into specific management strategies.

Table 3.1 Fishery sectors and the sampled number of units

Sectors	Total No. of units	No.of units sampled

4. Multi-species Model

As mentioned before, the most fishing ports of Karnataka have multi-species, multi-gear fishery. The single-species, static model presented in the previous sub-section is not adequate to incorporate the dynamic nature of fishery and multi-gear technical interactions into a management plan that is biologically and economically sustainable. A mathematical programming model is therefore used to represent the inter-temporal relationships between the stocks of various species and efforts exerted by fishing gears. The model will characterise optimal combinations of fleet effort levels and landings over time. Such optimal combinations of landings would result in the maximum net revenue from the given fishery subject to usual stock sustainability and other socio-economic conditions.

The model developed in the study could incorporate multiple objectives of a fishery management agency. Ideally, a public agency would like to optimise the combination of welfare accrued to fishery consumers (consumer surplus), producers (producer surplus) and labourers (wages). However, the main focus of this study is bioeconomic sustainability of fishery production. Also, productions from individual fishery management units, for instance, fishing grounds associated with ports, are not large enough to influence market supply and prices. Therefore, we do not consider the demand side of the market in the model. Thus included in the model is only the production side of a representative fishery.

The model explicitly considers alternative methods of fishing. The costs of operation and productivity vary between fishing methods. Fish stocks are assumed to be distributed uniformly across a given fishing area. Similarly, fishing effort by each gear type is assumed to be evenly applied across the fishing ground. Vessels of each harvesting technology target certain species, although there may be species overlap between two different harvesting technologies. For each period, the model keeps track of the effort applied by all vessel types toward each model species in terms of standardised fishing effort. Given this fishing effort, the total catch is determined using the catch-effort-stock relationship. For lack of better information and analytical simplicity, spatial (e.g., migration) and age structure aspects of fishery are ignored.

The model captures the dynamic nature of fishery through an inter-temporal stock growth equation. This equation balances the stock in each period to the previous period's stock plus net growth minus harvest. This gives the model the ability to track the impacts that the current fishing effort (technology and capital) has on future sustainability of fish stock. We can also impose a separate sustainability constraint that requires that each year's stock be more than or equal to the last year's stock. Through such constraint, one can analyse the trade-off between biological sustainability and social welfare impacts on fishing community.

Suppose that a public decision-maker attempts to maximise the following objective function:

$$\text{Max } Z = \sum_t \left(- \sum_v c_v E_{vt} + \sum_i p_i CT_{it} \right) \quad (4.1)$$

where Z is the value of the objective function; E_{vt} is the level of effort spent by vessel type v (actual fishing hour) in year t , CT_{it} is the quantity of species i caught (tonnes) in year t , c_v is the average cost of fishing by vessel type v (Rs/actual fishing hour), p_i is the market price of species i (Rs/tonne). The objective function is the sum total of annual revenues generated from all fish species *minus* the annual costs of harvesting.

The objective function is maximised subject to the following constraints (4.2) to (4.9) (Onal *et al.*, 1991). The total annual harvesting effort for each vessel type v and year t is constrained by available fleet capacity, $efmx_{vt}$. This capacity could vary over time.

$$E_{vt} \leq efm x_{vt} \quad \text{for all } v \text{ and } t \quad (4.2)$$

No fishery management agency would perhaps want to eliminate the entire fleet of an existing vessel technology at once. Therefore, a set of constraints that requires that fishery industry employ a minimum level of effort ($efmn_{vt}$) for each vessel class is included.

$$E_{vt} \geq efm n_{vt} \quad \text{for all } v \text{ and } t \quad (4.3)$$

The total catch of each given species is a result of efforts expended by multiple vessel types. In order to find the total effort directed toward a given species, we follow a two-stage computational process. In the first stage, we compute the constant proportion (d_{vi}) of total annual effort of vessel type v directed toward a given species i . This constant proportion can be derived by computing the ratio of the individual species catch of a given vessel type v to its total catch. Here we assume that the species distribution of effort of a given vessel is proportional to the species distribution of catch. The product ($d_{vi}E_{vt}$) is the effort of each vessel type directed toward a given species. We must note that the efforts of different vessel types are technologically different. Therefore, in the second stage, before we aggregate them in order to estimate the *total* effort toward a given species (TE_{it}), we need to convert the species-specific, individual vessel efforts to standardised efforts. A standardisation parameter s_v is computed by taking the ratio of the catch-per-unit effort (CPUE) of each vessel to that of the vessel class that has the highest CPUE. Thus, s_v for the vessel with highest CPUE is one and, for the rest of the vessel type, is less than one. Based on the above computations, added is the following set of constraints that sums up efforts exercised by all vessel types directed toward a species.

$$\sum_v s_v d_{vi} E_{vt} - TE_{it} = 0 \quad \text{for all } i \text{ and } t \quad (4.4)$$

The next set of constraints represents the standard non-linear catch-effort-stock relationship associated with every species and time period.

$$CT_{it} = \mu_i TE_{it} ST_{it} \quad \mu_i > 0 \text{ for all } i \text{ and } t \quad (4.5)$$

where CT_{it} is the quantity of fish species i caught during month t , ST_{it} is the natural stock of fish species i during period t , and μ_i is the constant parameter of the function. Specifically, μ_i is referred to as catchability coefficient, which represents the proportion of stock caught through a unit fishing effort. The above formulation is based on the Schaefer's (1954) assumption that the catch per unit effort or CPUE is a constant proportion μ_i of the stock. Onal *et al.* (1991) used a production function with constant return to scale of the type, $CT_{it} = \mu_i TE_{it}^\delta ST_{it}^{1-\delta}$. As they point out there

is no empirical justification for either functional form. Therefore, we use the more conventional formulation of the type (4.5) for this study.

The next constraint set balances the fish stock in the next period to the current period stock *plus* current period net recruitment *less* current period catch. Factors such as age structure, size, spatial location, and migration are ignored in this study for lack of better information and model simplicity.

$$ST_{it+1} = (1 + (\varphi_i - \eta_i ST_{it}))ST_{it} - CT_{it} \quad (4.6)$$

for all species i and year t except the initial period. The expression $(\varphi_i - \eta_i ST_{it})$ represents the density-dependent, annual rate of net growth of stock. φ_i and η_i are constant parameters. The initial year stock is exogenously set at user-defined levels ($inst_i$) for all species as

$$ST_{it} = inst_i \quad (4.7)$$

The primary fishery production sector must operate within the constraints of post-harvest processing and storage sector. This constraint can be added to the model via the following equation:

$$\sum_i CT_{it} \leq stor_t \quad \text{for each year } t \quad (4.8)$$

Finally, the model must comply with usual non-negativity constraints:

$$CT_{it}, E_{vt}, TE_{it}, ST_{it} \geq 0 \quad (4.9)$$

Data Analysis

The multi-species optimisation model is simulated for the Mangalore port. The Mangalore port is the largest fishing port in Karnataka, constituting 35 percent of the state's total fish landing in 1998. Seventeen most important species, which contributed more than 1.5 percent of the total port landing during 1994 to 1998, are included in the model. Based on the 1998 reported catch, these 17 species constituted more than 85 percent of the total fish catch in Mangalore (Table 4.1). The top five species harvested in 1998, in the order of their weight, are breams, Indian mackerel, stolephorus, sardine and cephalopods. For the same period, more than 10 different types of fishing vessel technologies are reported to have been

employed. For the purpose of this study, these vessel classes are regrouped into five homogenous vessel classes: mechanised trawlers nets (MTN), purse seiners (PS), trawler nets (TN), out-board fishing nets (OBU), and non-motorised boats (NMB).

The model requires three types of data: (a) economic data consisting of market prices, fishing costs, storage capacity, and labour requirement; (b) technological data including vessel-to-species effort conversion parameters, effort standardisation parameters, catchability co-efficient, and annual available fishing capacity; and (c) biological data that include initial period stock estimates and growth parameters.

Market price data for the selected species are collected from the field observations (Table 4.1). The costs per actual fishing hour (AFH) are computed using data from a primary survey of different fishing firms. The method employed for computing the AFH costs for each fishing technology is explained in Chapter 3. The costs included are fixed cost (interests, insurance, maintenance, and depreciation), operational costs (cost of fuel, ice, auction marketing, labour and port charges) and crew share. Based on this computation, the unit fishing of costs are estimated at in Rs/AFH 410, 919, 460, 70, and 100 for technology classes MTN, PS, TN, OBU and NMB respectively. However, these costs represent the efforts that landed all the reported species in the port. For certain individual vessel classes, particularly for OBU and NMB, the species included in the model represent a small portion of the vessel's total effort (Table 3.2). The unit costs are therefore prorated based on the proportion of the vessel's effort directed toward the model species. The prorated unit costs of fishing are in Rs/AFH 368.63, 824.42, 395.96, 37.50 and 60.02, respectively (Table 4.2).

Table 4.3 presents the parameters that convert a unit effort of each vessel type to effort directed toward model species (d_{vi}). These parameters are computed by taking the ratio of the five-year total of individual species catch (1994-98) to the total catch reported for the same period for that vessel class. Also reported in the table is the effort standardisation parameter (s_v) that converts effort by each vessel class to a standard unit of effort. These standardisation parameters are derived by

computing the ratio of the CPUE of each technology class to that of purse seiner vessel, which has the highest CPUE.

The catchability coefficients for most model species of Mangalore port are assumed to be the same as the estimates developed for the Karnataka state in the previous chapter. For certain model species, state-level estimates are not available. The catchability coefficients of most closely related species are used for such species. See Table 4.4 presents the estimates of these coefficients. The annual capacities of fishing vessels in AFH are assumed at the 1998 levels, which are reported in Table 3.4

The initial year exogenous stock levels are computed using the Fox model (equation 3.1). For using the Fox model, the 1998 levels of standardised effort are first computed for each model species of Mangalore port. These standardised effort values along with the estimates of catchability co-efficient (Table 4.4) and the observed quantities of species catch (Table 4.1) are plugged into the Fox model equation to estimate the initial year stocks (see Table 4.4). However, when we run the baseline simulation model, to be discussed later, our goal is to make sure that the model-generated catch values come as close to matching the observed catch values for the year 1998. Of the four variables above, catchability co-efficients are estimated using the state-level data of 10 years, which we think are more reliable than the initial year stocks estimates for Mangalore. The 1998 observed catch and effort values are certainly more accurate than the unobserved stock estimates. Therefore, for the purpose of this analysis, we calibrate the initial exogenous stock values so that the baseline model generates species catch distribution as close to the 1998 observed catch distribution as possible.

The data on the intercept and slope parameters of the annual net growth function (φ_i and η_i) are not easily available. Therefore, for lack of better information, these parameters are based on our best educated guess. The values are reported in Table 4.4.

The mathematical programming model is solved using the Generalised Algebraic Modelling System (GAMS) software (Brooke *et al.*, 1998). This software has a routine for solving non-linear programming models. The model is run for a period of

10 years with annual increment. The baseline model has a total of 663 equations (belonging to 11 separate blocks of equations), 563 variables, and 2362 non-zero elements. The model could be run easily on a Pentium PC computer. Various sensitivity analyses also are carried out to evaluate various management and policy scenarios. See Appendix I for the GAMS program code for the model simulations.

Results and Discussion

Baseline Model and Validation

Before a model can be used for any meaningful policy and management analyses, the model results must first to be validated with reference to some historical or observed outcomes that the model is trying to predict. In an optimisation model like the current one, validation cannot be done by simply comparing the model-estimated values with some historical values since the model optimises effort and catch (Onal *et al.*, 1991). The reason is that the observed values may not be optimal to begin with. Alternatively, we force the endogenous effort levels for all the model years to be equal to the observed effort level of 1998 (Table 4.1). Then we compare the 1998 model catch values and the observed catch values. We call this the baseline simulation. This effort restriction on the model also allows us to understand how harvesting at the current effort level would impact the sustainability of the fishery stock and catch.

Table 4.5 and 4.6 present the results of the baseline simulation. Comparison of the 1998 observed catch and the model-estimated catch is made in Table 4.5. For most species, the differences between the model and observed levels of 1998 catch are within 11 percent. For ribbonfish and stomatopods, the difference is around 18 percent of the observed level. For black pomfret, there is a wide relative gap between the two values. There was a wide year-to-year fluctuation in the pomfret catch during 1994 to 1998. Also, this is one of the least significant model species in recent years. There may be errors in the specification of the unobservable biological parameters, and errors in collecting the third party data on catch and effort. Given these factors, we consider the model's overall performance quite satisfactory.

In the baseline simulation, the stocks of 9 out of 17 model species decline over time. These are Indian mackerel, rock cods, bream, ribbonfish, other carangids, black

pomfret, prawns, stomatopods, and cephalopods. Stocks of six species viz, sardine, stolephorus, thryssa, other perches, and soles--increase. Stocks of two other species viz, other sardines and scads remain stable. The most interesting results to watch is mackerel. This species would become most unsustainable in terms of both stock and catch in 10 years if the exploitation continues at the current effort intensity. Mackerel, which is only second to breams in catch with 5,246 tonnes in 1998, experiences more than 40 percent reduction in catch. Similarly, other species that suffer drastic decline in stock and catch are prawns, stomatopods, and cephalopods.

The baseline harvesting results in total market revenue over 10 year period of little over Rs.4,929 million, whereas the total cost of harvesting is as high as Rs.4,844 million. That leaves a net fishery rent of only Rs.84 million or 1.7 percent of the total market revenue. Relative to the total market revenue, the rent margin under current harvesting scenario is insignificant. The crew-members salary is estimated at Rs.1,391 million or 28.23 percent. Since the declining species are mostly caught by trawlers, both mechanised and multi-day, the trawler industry would more likely be affected by this decline. Concurrently, the employees of this industry would be adversely affected too.

Optimal Fishery Harvesting

Our next goal is to run the model to characterise the optimal combination of vessel efforts. We run the simulation again without forcing endogenous effort values on the model like in the baseline run. Only restriction we would put is the minimum and maximum constraint on the effort. Minimum effort constraint is included to reflect the political reality that no single vessel class could be completely eliminated from the fishery. The maximum constraint is necessary to avoid the model to become unbounded. Also, there are real-world capital constraints on the limits to which fishery capital can expand in a given time period. The maximum fishing efforts are assumed to be 25 percent above the 1998 observed level for all vessel classes except NMB. For the latter, the effort restriction is placed at twice the current level. The minimum efforts are assumed at 50 percent of the current level.

The results of the optimal harvesting simulation are presented in Table 4.7, 4.8 and 4.9. While there is still some degree of over fishing in some cases, the stocks of all

but four species either increase or remain stable. Indian mackerel, black pomfret, stomatopods, and cephalopods still experience a decline in the stocks. However, the rates of this decline, particularly for stomatopods, and cephalopods, are much slower than that they experience under the baseline scenario. Interestingly enough, the rates of stock and catch decline for Indian mackerel remain the same as the rates under the baseline situation. This is because of the fact that under the optimal scenario, the number of fishing hours by PS, the effort of which are mostly dedicated mackerel, increases quite substantially. This increase in PS effort is offset by any reduction in the effort by other vessel classes, for instance, OBU.

Another interesting finding is that the optimal model results show that there is almost no change in the total value of harvest (Rs. 4,969 million) from that of the baseline simulation (Rs. 4,929 million). However, there is a substantial reduction in the cost of fishing from the baseline level of Rs. 4,844 million to the optimal level of Rs. 3,155 million, resulting in a profit of Rs. 1,814 million or 36.50 percent of the total market value (Table 4.10). This is due to both biological and economic reasons. Biologically, more number of species become either sustainable, stable or less unsustainable over the ten-year period under the optimal scenario. This certainly increases the total catch of certain species. Economically, the model allocates effort more toward high value species and high-productivity (or unit cost) vessel. This helps the fishing industry realise higher rent from fishery. Thus, the optimal effort distribution not only increases fishery rent but also increases the chance of several model species to become either sustainable or more sustainable.

Biological and Economic Changes in Fishery Stocks

It is insightful for fishery managers to carefully look at the long-term effects of certain harvesting regime—current (baseline) or optimal harvesting strategy—in terms of biological and economic value appreciation of fish stocks and their catches. Table 4.10 presents the changes in the stock and catches due to the continuation of the baseline effort (1998 level). Seven species, which are commercially most important, such as stomatopods, Cephalopods shrimp, mackerel, ribbonfish and carangids experience depreciation in stock and catch by the year 2007. Some of the important export oriented species such as stomatopods and Cephalopods undergo loss in stock to the extent of 100 percent, followed by shrimp (78 percent), ribbonfish (68 percent)

and mackerel (42 percent). The estimated catch levels of these species also decrease by corresponding percentage in 2007.

The table 4.11 shows the improvements in the stock and catches with the adoption of the optimal harvesting strategy. Though, some of the species still undergo depreciation in stock and catch between the initial year and terminal year (i.e., year 2007), the rate of decrease is considerably less than that are experienced under the baseline model (table 4.10). The stock (catch) of commercially important species such as shrimps, which would depreciate to an extent of 78 (78) percent under the baseline model, decreases by only 5 (46) percent under the optimal model. The rate of decline of ribbonfish was only 5 percent in stock and 47 percent in catch under optimal model. Further, the stocks and catch levels of several other species have considerably improved showing a positive impact of the optimal harvest strategy.

The table 4.12 shows the year-to-year percentage change in the economic value of a few selected species under both baseline and optimal scenarios. The percentage addition in the economic value decreases in the course of the period up to 2007, indicating that under a long term scenario most of the species become less and less sustainable. However, a comparison between baseline and optimal model shows that the economic value addition for each species is much higher for many of the species under optimal model indicating better management compared to baseline situation. The threadfin breams, rock cods, lizardfishes, ribbon fish, soles, shrimps, stomatopods, cephalopod improve their sustainability considerably under optimal model. On the other hand mackerel and pomfrets undergo higher loss over the years under optimal model compared to baseline model. The shrimps, which would decrease at the rate of 11 percent under baseline model, changes its path and we can observe the improvement in its sustainability and percentage rate of change in its economic value become positive.

Analysis of Alternative Management Policies

The fishery management policies in India are broadly governed by the Indian Fisheries Act of 1897 and the marine fisheries (regulation) acts of the respective states which were enacted in the eighties. The Karnataka Marine Fisheries (Regulation) Act of 1986 provides for the regulation of fishing through seasonal

closure of fishing operation by specified vessels, restriction of fishing in specified areas and control of indiscriminate fishing of brood stock and juveniles through regulating mesh size. For example in Karnataka, fishing by mechanised fishing vessels are prohibited from fishing during monsoon season for two to three months. However, most part of the Act has not been implemented due to the lack of information on the impact of such policy measures on different stakeholders. In this section, we calibrate our model to simulate the impacts of various fishery regulation policies such that the results of the simulation will help to shed light on how the unsustainable harvesting as seen in the baseline or optimal fishery simulations can be corrected. For the purpose of the analysis, we consider two policy scenarios:

Policy Scenario I: Under this scenario, we analyse the effects of placing restrictions on harvesting technology that reduces the harvesting capacity of purse seiners. Both under the baseline and optimal harvesting scenarios, this vessel type is found to promote an unsustainable harvesting of mackerel, one of the commercially important pelagic species. The technology restriction may be implemented by changing the mesh size of nets that are used on this vessel. This policy change represented in the model by reducing the effort standardisation parameter for purse seiners from the baseline level of 1.0 to 0.7.

Policy Scenario II: For this scenario, a seasonal restriction of two months on all mechanised vessels such as purse seiners, trawlers and outboard fishing nets is considered. This policy allows stocks to rejuvenate during the spawning season and directly impacts the total annual effort expended by fishers. Moratorium on harvesting is most common under the Karnataka laws. Therefore, maximum effort constraints are reduced by 2/12 of the baseline levels for the above vessel types.

Table 4.13 and 4.14 presents the estimated values of stocks of selected species, gross returns, total cost, net profits and wage payments under policy scenario I and II. The initial stock (actual stock in 1998) presented in the table allows comparison of the effectiveness of each of the policy options in enhancing stock levels and also economic costs and returns. It is clear that the two policy options have different impacts on individual species. For most of the species both scenarios will result in much higher stock levels through the year 2007 than the optimal harvesting scenario discussed earlier, except in the case of species such as stomatopods and

cephalopods. It is interesting to note that under the optimal harvesting plan, there is a decrease in the mackerel stock to almost half of the initial stock. However, each of the policy scenarios discussed here shows an improvement of the stock. The stock of the oil sardines and stonefish also improves under both the scenarios.

It could be observed from the table that some of the species which, are unsustainable under optimal harvesting scenario (Table 4.12) such as prawns, pomfrets and scads becomes sustainable under each of the policy scenarios discussed. The sustainability of prawns, which is one of the most highly targeted species by the trawlers, improves under Scenario II and I. The stock level of scads, which was reduced under optimal harvesting strategy to 10613 tons from the initial stock of 13000 tonnes increases to 14799 tonnes under Scenario I and to 12843 under Scenario II respectively.

As expected, the economic returns accruing to fishermen and payment to labour are slightly lowered under the subject scenarios. The gross returns diminished from Rs. 4.97 billion under the optimal harvest level to 4.21 billion and 4.56 billion under Scenario I and Scenario II, respectively. Similar trend can be observed with respect to labour payment. The total cost of harvesting also slightly decreases from Rs. 3.16 billion under optimal harvest levels to 2.93 billion in Scenario II due in most part to reduced fishing effort for two months.

All though two-month moratorium on fishing effort (scenario II) improved long-term stock levels of most species considerably, the major species of the Mangalore port such as Indian mackerel experiences a setback in stocks by the end of the simulation period by as much as 25 percent. High value species like cephalopods and stomatopods also lose their stock level significantly. It is clear that the current policy of seasonal restriction of two months is not fully potent in stemming the unsustainability of problem of at least some major species.

Conclusion

The results of the single species model estimated the sustainable yield and maximum economic yield without considering interactions between stocks, species, gears, labour, processing and marketing factors. On the other hand, multi-species model presented in this section incorporated the dynamic nature of the fishery and

multi-gear technology interaction into a management plan in order to assess biological and economic sustainability. We conducted several simulations of the model. In the baseline model the endogenous effort level was forced on all the future ten years based on the observed effort level of 1998. This effort restriction enables us to understand the future sustainability of catch and stock given the current effort level. The result of the baseline model shows that stocks of most of the model species are declining over the period. The mackerel, which is one of the most important pelagic species, clearly suffers unsustainability in the future catch and stock if the current effort level is continued.

The optimal simulation is developed without current level effort restrictions. The results of the optimal model reveals declining stock levels of selected model species such as mackerel, cephalopod, stomatopod. The estimated total revenue from both the models are almost same. But cost of harvesting from the baseline level to optimal level decreases by 54 percent and hence profitability increases by 21 percent. Thus by promoting the effort combination, the biological and economic sustainability can be improved.

The above results clearly support the view that the fishing industry in Mangalore spends a way too much effort and cost to realise their market income. Through optimal re-distribution of its effort, the same market value of fishery output can be obtained at almost 35 percent less cost (Table 4.10). For the optimal scenario, the amount of labour payment is estimated at Rs. 1,425 million, only a slight increase from the baseline estimate (Rs. 1,391 million). Since the wage payment is a fixed portion of the market value of catch, and the total revenue does not change much, this small increase in the wage is reasonable.

Table 4.1. Quantity of catch (tonnes) by Model species and fishing units for Mangalore port, 1998

5. Conclusions and Recommendations

The marine fisheries of Karnataka are one of the major sectors contributing significantly to the income and employment of the regional economy. Over a period of 30 years the industry has undergone technological change and has moved from the subsistence to commercial status. This modernization has resulted in the growing signs of unsustainability. The negative growth rate in marine fish production during 1990s showed the symptoms of over harvesting. The state government though passed marine fisheries regulations to impose limited entry into fishery, it could not implement the provisions of the act due to possible socio-economic impact of such a measure. The present study is an attempt to study the biological and economic sustainability of the Karnataka marine fishery under alternative scenarios. Some of the important conclusions of the study are presented.

1. The increase in fishing effort during 1970s and 1980s has led at first to rapid increase of commercial landings, which grew at the rate of 2.6 % and 5.95% until early 1990s. During 1990s there was a negative growth of total production. Legal framework to control the fishing efforts was not enforced for socio-economic reasons.
2. In order to study the biological and economic sustainability of the Karnataka fishery, to help fishery management authority to limit the effort level single species model was constructed. The results of single species model, shows that most of the species are harvested at very close to maximum sustainable yield levels and above the maximum economic yield.
3. Multi-species mathematical programming model implemented for representative Mangalore port estimates the response of stock and catch levels under various scenarios. The objective function was to maximize the net benefits from a fishery given a set of constraints. The results of baseline simulation model with forcing of 1998 effort level on the next 10 years shows that the most of the model species are biologically and economically unsustainable. The policy simulation of effort restriction and seasonal moratorium indicate that these policies do help sustain some species, but fail

to protect most popular species like Indian mackerel and high value species like cephalopods and stomatopods.

Recommendations

As shown by the results, we cannot expect to get increased catches by simply increasing fishing effort. On the other hand, we can improve the sustainability by changing exploitation pattern. At present the fisheries exploitation is based on fishing through trawlers of different types. However, by encouraging some the fishing techniques such as purse seining and administering the proper mesh size the efficiency of harvesting can be achieved. It is possible to achieve important economic and biological benefits by proper re-allocation of fishing effort and keeping fishing cost at their minimal level.

Further, rebuilding of stocks through increased mesh size, closing areas and seasons for fishing at least for destructive fishing the sustainability can be improved.

Description of species-by-species

Table 1 Classification of the selected species

<u>Demersal species</u>	<u>Pelagic species</u>
Halibuts	Tunnies
Threadfin breams	Seer Fish
Rock cods	Scads
Cat fish	Horse Mackerel
Rays	Wolf herring
Pomfret	Stolephorus
Soles	Indian mackerel
Shrimp (paneied prawns)	Oil sardine
Shark	Hilsa Shad
Lizard fish	

Indian Oil –sardine

Oil sardine is the most important resource in the neritic pelagic zone off the west coast of India. The coastal areas between Kerala and the Karnataka are rich in traditional fishing grounds for the Oil-sardine, although in certain years its commercial abundance extends to other sections of the west and east coast. The annual average catch of Oil-sardine for 1994 was 1,01,677 tonnes forming 3.76% of the total marine fish catch of India and 2,03,909 tonnes forming 7.6% of the total marine fish catch of India (26,69,480 tonnes) in 1998. During the year 1999 the oil sardine received a higher landing. The landings increased from 2,03,909 tonnes in 1998 to 2,40,978 tonnes in 1999, an increase of 18.18 percent. The oil-sardine ranks as one of the best-known commercially important fish of India and is commonly used as food in the fresh and cured conditions.

Oil sardines are mainly caught with two types of nets - the boat seine and gillnet. In Karnataka, rampani was the major gear of exploitation before the introduction of purse seiners. During the mid seventies, purse seiners replaced the traditional gears like rampan, which helped in increasing the oil- sardine landings.

Indian Mackerel

The mackerel is a pelagic fish in neritic waters and its oceanic phase is little known except that it is caught in deeper waters by fishing trawlers occasionally. It is a shoaling fish, not moving singly or in small schools of a few members but in appreciably large numbers spreading over a wide area and moving steadily in one direction.

Indigenous crafts and gears employing traditional methods mostly exploit the mackerel, but the introduction of the mechanized boats has greatly affected the catch rates of traditional small-scale gears. The basic types of gears viz., boat seine, drag nets or beach seine, gill nets of several types including drift nets and the cast nets and types of craft viz, dugout canoes, canoe boats, plank-built boats and catamarans are employed for the capture of mackerel in different states along the west and east coasts. Among the mechanized boats the purse seines followed by trawl nets harvest more than 80% of the mackerel.

The annual average catch of mackerel for 1993 was 2,49,186 tonnes forming 11.10% of the total marine fish catch (2,245,124 tonnes) of India and in 1998 it was found to be 1,77,172 tonnes forming 6.64% of the total marine fish landings (26,69,480), as reported by CMFRI. The landings increased from 1,77,172 tonnes in 1998 to 2,09,741 tonnes in 1999, an increase of 18.38 percent.

Anchovies

Most Anchovies are marine, but some can tolerate low salinities or even fresh water. Although usually small, many are shoaling species of great importance to fisheries; some are used for food, others for bait. During 1990, the reported catch for anchovies in India totaled about 110 tonnes.

It's a valuable marine fish as a source of food and fish meal and is also suitable for salting and sun drying as well as canning. In the years when both the sardines and the mackerels are scarce, the anchovies are in plenty in our waters. In India, they occur all along the east and west coasts. The Purse seine, and trawl nets are used for harvesting anchovies.

Stolephorus

Stolephorus is a pelagic marine fishes always with a distinct silvery lateral band. Purse seines and trawlers are use to harvest this species. These fishes are the most important among the anchovies. In 1990, the reported catch for stolephorus in India totaled about 70,741 tonnes. The landings decreased from 72,637 tonnes in 1998 to 49,543 tonnes in 1999, a decrease of 31.8 percent

Thryssa

This is a small-sized anchovy and good catches of this fish are obtained on the Andhra coast during February and from June to September. It also constitutes a fishery along the coasts of Kerala and Tamil Nadu from June to September. These are caught using seines and stake nuts. The landings decreased from 42,231 tonnes in 1998 to 31,547 tonnes in 1999, a decrease of 25.24 percent

Lizard fishes

The lizard fish do not form an important independent fishery but are caught in small quantities, forming a supporting fishery to the other major fisheries. They are normally considered in the category of demersal fishes.

These fish are relished as food in fresh as well as in dry condition by poor people. Most of the lizardfishes are inshore shallow-water forms, usually living on sandy or muddy bottom adjacent to rocky or reef areas.

Edible, but of poor quality. In India, they occur all along the west Pacific coast. The annual catch was 20,378 tonnes during 1994. The landings decreased from 24,115 tonnes in 1998 to 17,707 tonnes in 1999, a decrease of 26.6 percent. The types of nets used in the lizard fishery are gill net boat seine and purse seine. Lizard fishes are also caught in trawls operated up to 30 fathom depth.

Threadfin breams

These are small to moderate sized, slightly compressed fishes and inhabit shallow coastal waters of the tropical Indo-pacific; most brightly colored and geographically distributed around south-east coast of India, through the East

Indies, to the Philippines and Australia. The fishery is of minor significance on the Tamil Nadu coast. Trawl is the principal gear of exploitation. The landings decreased from 81,340 tonnes in 1998 to 73,994 tonnes in 1999, a decrease of 9 percent.

Ribbonfish

Ribbon –fishes are poor quality food fish and constitute one of the important commercial fisheries in India. The annual catch was 1,13,883 tonnes during 1998 forming 4.23% of the total landings. The landings increased from 113883 tonnes in 1998 to 124548 tonnes in 1999, an increase of 9.37 percent.

These fishes are caught almost all along the Indian coast and form an exclusive fishery of considerable magnitude at several places, especially in the southern peninsula region; the states of Andhra Pradesh, Tamil Nadu and Kerala account for the the grater percentage of annual catches. The usual gear for these fishes is the boat-seines.

Carangidae

This family contains some very important food fishes and plays a significant part in the commercial fisheries of our region. These fishes constitute a fairly high proportion of the catches both on the east and west coasts of India. The carangidae form an important demersal fishery resource along the Karnataka coast, accounting for 5.17% of the total marine landings (Govt. of Karnataka, 1997). The landings decreased from 147474 tonnes in 1998 to 126297 tonnes in 1999, a decrease of 14.36 percent.

Horse mackerel, scads and leather-jackets belong to the family of carangidae, white leather jacket belong to the family Aluteridae.

Pomfrets:

Pomfrets are excellent table fish, much relished and highly priced. In India they support important fisheries both along the west coast and the east coast regions. They are found on the continental shelf at all depths, generally up to 100

fathoms. Like many other groups of coastal fishes, pomfrets often enter the estuaries and brackish water zones. They occur widely in the Indo-west pacific. In the 22-year period (1958-79) pomfrets formed an average of 2.4 percent and in 1993 1.86 percent (i.e. 41,767 tonnes out of 22,45,124 tonnes of total landings) of the all India annual landings of marine fish.

More over, the landings decreased from 49364 tonnes in 1998 to 34009 tonnes in 1999, decrease of 31 percent.

They are harvested using multiple types of gear right from shore seine to deep-sea trawlers.

The Flat fishes:

Flatfishes are characterized by their dorso-ventrally compressed body with eyes sinistral or dextral. This group of fish, specialized in bottom dwelling/burrowing habits includes *halibuts, flounders, and soles*.

The soles, though they occur along both the coasts of India, constitute a fishery of considerable importance along the Malabar Coast, next to the oil-sardine, mackerel and prawn fisheries. They contain less fat and hence are suitable for quick drying and preservation.

Soles:

These include mostly small fishes found in all but the coldest seas, from the shore to fairly deep-waters. Many are of importance, highly esteemed as food.

Seer fish:

Seer fish fishery in India is supported by three commercially important species, *Scomberomorus commerson, S. guttatus* and *S. lineolatus*. Seer fish have white flesh with high fat content. Being highly esteemed fish, they have great demand in inland as well as foreign market. Besides, they are important, being available along both the coasts of India.

Diverse crafts gear are employed in the seer fish fishery. Both mechanized and non-mechanized boats are deployed along the Gujarat Maharashtra and

Karnataka coasts. Gill nets and hooks and lines are the principal gear used for seer fish. Besides, they are also caught in appreciable quantities in other types of gear used for different fishes.

Tunnies:

The tunas comprise a highly valued group of fish, the meat of which either in fresh or processed state is much in demand all over the world. They are tropical and subtropical in their distribution in the world oceans and their occurrence is by far greater in the oceanic waters beyond the territorial limits of the fishing nations than in the coastal waters. They are very much under fished from Indian coasts. Tuna fisheries are of international importance as these resources occur in all the world oceans. The tuna catches of India are mostly obtained from the inshore waters. Much of the tuna catch is consumed in fresh condition. It is transported chilled in ice or cold stored before marketing. Part of the catch is brine cured and sun-dried.

Cephalopods:

The cephalopods belong to the family of Molluscs, occurring in abundance in the shallow coastal waters of the seas, estuaries and brackish water habitats. Annual fluctuations in cephalopod landing in India are very marked. In the nine year period (1971-79) the lowest catch of cephalopods was 1026 m.t. in 1972 forming 0.104 percent of the total marine fish catches estimated at 980,049 m.t. and the highest was 15,931 m.t. in 1978 forming 1.14 percent of the total marine fish of 1,403,607 m.t. Kerala, Maharashtra and Tamil Nadu rank high in the order of abundance. Karnataka and Andhra Pradesh rank next with moderate catches. An export trade in what is known as the "squid fingers" is being built up. As an item of food some of the members of the same species after cephalopods are utilized as food items. In 1994 these formed 3.54 percent of total marine fish landings of 27,07,439 tonnes.

Catfishes:

Catfishes are scaleless bony fishes inhabiting marine, estuarine and freshwater habitats. They generally prefer muddy grounds. The commonly important catfishes are marine forms. The catfishes are landed by different types of seine nets and hooks and lines by indigenous non-mechanized craft and in trawl nets operated by powered fishing vessels. In 1994 they formed 3.2 percent of total annual Indian marine fish landings of 27,07,439 tonnes.

Elasmobranches (Shark, Rays and Skates):

Elasmobranches form one of the important commercial fisheries of India, in 1994 forming 3.1 percent of total annual Indian marine fish landings estimated at 2707439 tonnes. They widely distributed in the tropical, subtropical and temperate water of the seas around the world. Although they are essentially marine, a few species enters the estuaries. A very large number of species of sharks, skates and rays occur in the Indian water supporting fisheries. They form an appreciable proportion in total annual marine fish landings of the country (3.2 to 6.5 percent in the past two decades). Some species yield quantities of liver oil of medicinal value because of their high vitamin A content. The skin of sharks suitably tanned can be used as leather. Elasmobranches are caught in types of gears operated by the mechanized and the non-mechanized crafts in coastal waters in fair abundance usually upto about 30 mt. depths.

The Ministry of Environments and Forests of the Government of India, considering the over harvesting of some of the rare species such as whale sharks included it in the Schedule I of the Wildlife Protection Act. The whale shark is the first species to get protection under the Act. After including the whale shark in the negative list, it is expected that the official exports are likely to come down. However, underground exports are likely to flourish unless the whale fishermen are properly rehabilitated.

Wolf-herrings:

These compose a single Indo-Pacific genus, *Chirocentrus* with two species as representatives. Wolf-herrings are voracious carnivores. Their contribution of about 8000 tonnes to India's annual total marine fish catch forms about 1 percent (1984).

Shrimps

The shrimps are of the most targeted species due to its high value in the international market. A major portion of the landings is exported in frozen form to US, Japan and European markets. The shrimps are mainly targeted by trawl nets. The production of shrimp increased from 188755 tons in 1985 to 242425 tons in 1993. However, thereafter the total shrimp production in India stagnated around 320023 tons until 2000. The large-scale trawl fishing caused the shrimp biomass to diminish dramatically in these regions. Reduction in the shrimp biomass could also be to changes in the sea conditions.

Hilsa (shads)

It has considerable economic importance in India and Pakistan, Bangladesh and Burma. The esteem to which the 'hilsa' is held in Bengal is reflected in the many references to its quality and flavor in Sanskrit and Bengali literature. This is one of the best known of Indian clupeids and is a migratory fish ascending all the major river systems, where it was caught in considerable quantities.

Lobsters

In addition to the recent demand for lobsters from big catering organizations, the lobster market has come into prominence mainly because of the exports. The market is still expanding but the supply of Indian lobsters is not commensurate with the demand, as India has to face stiff competition because of increasing demand for live lobsters. On the south-western coast of India the three types of gear in use are lobster traps, anchor hooks and scoop nets.

Lobster fishing with all these three gears is carried out at night. In the north, west Maharashtra and Gujarat coast fixed nets, traps and drag nets are the common gears used.

Annexure II

GAMS Program

Sustainable Harvesting of Multi-species in Karnataka Marine Fishery

This is a multi-period problem of estimating of environmentally and economically sustainable levels of harvesting multiple species of marine fisheries using multiple fishery technologies.

The project was funded by the World Bank and administered by IGIDR.

The programming software support was given by the GAMS Development Corporation, Washington, DC.

THIS PROGRAM SIMULATES 'BASELINE' and 'OPTIMAL HARVESTING' SCENARIOS

Sets
